1 **Abstract**

2 As the offshore exploitation moving to deeper waters, ocean currents would become
3 more prevailing hydrodynamics on pipelines, and meanwhile the sloping seabed is
4 always encountered. The prediction of lateral soil resistance is vital in evaluating the
5 pipeline on-bottom stability. Unlike the previous pipe-soil interaction models mainly
6 for horizontal seabed conditions, a pipe-soil interaction model for current-induced
7 downslope and upslope instabilities is proposed by using limit equilibrium approach.
8 The Coulomb's theory of passive earth pressure for the sloping seabed is
9 incorporated in the derivation. The model verification with the existing full scale
10 tests shows a good agreement between the experimental results and the predicted
11 ones. Parametric study indicates that the effect of slope angle on the pipeline lateral
12 soil resistance is significant in the examined range of the slope angle from -15° to
13 15° . The critical pipeline embedment and the corresponding passive-pressure
14 decreases approximately linearly with increasing slope angle.

16 study; Pipe-soil interaction; Sloping seabed

17

18 Introduction

19 Lateral soil resistance is one of the fundamental issues in submarine pipeline
20 on-bottom stability design for the hydrodynamic loading conditions in offshore
21 environments (Wagner et al. 1989; Det Norske Veritas 2010). The behavior of the
22 pipeline on-bottom instability in ocean environments is a complex phenomenon,
23 involving significant flow-soil-structure interaction. Unlike the conventional
24 foundations of structures, on-bottom pipelines can tolerate moderate movements
25 across the seabed without exceeding a limit state, except where they are constrained
26 by wellheads, other connections or obstructions on the seabed (Randolph and
27 Gourvenec 2011). As the oil and gas exploitation moving into deeper waters, ocean
28 current becomes one of the prevailing hydrodynamic loads on submarine pipelines.
29 Besides the usual steady current, a turbidity current fast-moving down a slope
30 can incise and erode continental margins and even cause serious damage to
31 engineering structures. The interaction of internal waves with the seabed is another
32 significant source of near bed currents (Boczar-Karakiewicz et al. 1991). It is noted
33 that the submarine pipelines are more preferred to be laid directly on the seabed
34 (seldom buried artificially) in deeper waters. Meanwhile, the submarine slopes are
35 always encountered, e.g. at the continental slopes in South China Sea (Liu et al. 2002).
36 As such, an improved understanding of the mechanism on current-induced instability
37 of unburied pipelines on a sloping seabed would be beneficial to offshore engineering
38 practices.

39 When ocean currents are in perpendicular to the axis of a horizontal pipeline

40 which is partially-embedded in the sloping seabed with certain slope angle (α), the
41 flow-induced pipeline on-bottom instability can be regarded as a plane strain problem
42 (see Fig. 1). There normally exists a balance between hydrodynamic loads (including
43 drag force, F_{Du} , and lift force, F_L), the submerged weight of the pipeline, W_s , and the
44 soil resistance, F_{Ru} . If the soil lateral resistance to the pipeline could not balance the
45 hydrodynamic loads and the submerged weight, the pipeline would break out from its
46 original locations, i.e. the lateral on-bottom instability occurs. Thus, an accurate
47 prediction of the ultimate lateral soil resistance is vital for properly evaluating the
48 on-bottom stability of the pipeline partially-embedded on a sloping seabed.

49
50 **Fig. 1. Illustration of the current-induced pipeline lateral instability on a sloping**
51 **seabed: (a) Downslope instability; (b) Upslope instability**

52
53 The conventional interfacial frictional theory (i.e. Coulomb friction model) was
54 ever suggested to predict the lateral soil resistance of the pipeline (Lyons 1973).
55 Previous pipe-soil interaction tests (Wagner et al. 1989; Brennodden 1989; Gao et al.
56 2007, 2011) showed that the loading history that increased the pipe penetration led to
57 a notable increase of the lateral on-bottom stability. The soil berm ahead of the pipe
58 provides passive resistance, which governs the lateral pipe-soil interaction force
59 (White and Cheuk 2008; Youssef et al. 2013). Hence, the soil resistance is far more
60 complex than the simple interfacial friction that calculated using the conventional
61 Coulomb friction model. A literature review on physical modeling of pipeline

62 on-bottom stability can be referenced in [Gao et al. \(2012\)](#). The existing test data
 63 indicated that the lateral resistance was significantly dependent on pipe penetration
 64 and soil strength.

65 An empirical pipe-soil model by [Wagner et al. \(1989\)](#) has been adopted for the
 66 dynamic lateral stability analysis in the current DNV Recommended Practice for
 67 on-bottom stability design of submarine pipelines ([Det Norske Veritas 2010](#)). Their
 68 model was based on the results of a series of pipe-soil interaction tests. The lateral
 69 resistance (F_R) was estimated by the model including the following two components,
 70 i.e. a sliding-resistance component (F_{Rf}) plus a passive-pressure component (F_{Rp}):

$$71 \quad (1) \quad F_R = \underbrace{\mu_0 (W_s - F_L)}_{F_{Rf}} + \underbrace{\beta_0 \gamma' A_{0.5}}_{F_{Rp}} \quad (\text{for a horizontally flat sandy seabed})$$

72 where μ_0 is the sliding resistance coefficient, which was set as 0.60 for the pipe on
 73 sands; W_s is the submerged weight of the pipe per unit length (in kN/m); F_L is the
 74 hydrodynamic lift force on the pipe per unit length (in kN/m); γ' is the effective
 75 (buoyant) unit weight of the sand (in kN/m³); $A_{0.5}$ is a characteristic area which can
 76 be calculated from the initial estimated penetration, i.e. one half of the vertical cross
 77 sectional area of the soil displaced by the partially-embedded pipe (in m²); β_0 is a
 78 dimensionless empirical coefficient for the soil passive pressure, which is relative to
 79 the sand density and the loading history. For the simple monotonic lateral loading,
 80 the values of β_0 were recommended empirically with a wide range, from “38” for
 81 sands with $\gamma' < 8.6$ kN/m³ to “79” for sand with $\gamma' > 9.6$ kN/m³. It should be
 82 noticed that a direct sum in the scalar form of the sliding-resistance and the
 83 passive-pressure components (see [eq. \(1\)](#)) was not appropriate for describing the

84 actual pipe-soil interactions. In the existing empirical lateral pipe-soil interaction
85 models (e.g. the aforementioned model (eq. (1)), and an energy-based pipe-soil
86 interaction model by [Brennodden et al. \(1989\)](#)), the ultimate lateral soil-resistance to
87 the partially-embedded pipeline has not been well understood.

88 Historically, plasticity theory has been used for calculating the lateral earth
89 pressure on conventional retaining walls, which is a central issue in the analysis of
90 retaining structures. In the plasticity analysis, a zone of soil is assumed to reach its
91 plastic equilibrium such that plastic collapse occurs. This plastic soil zone slips
92 relative to the rest of soil mass along the slip surface, where the peak soil strength is
93 assumed to be mobilized ([Osman and Bolton 2004](#)). The full range of soil strengths
94 can be expressed in terms of the variation of shearing resistance angle (ϕ) with
95 density and confining pressure ([Bolton 1986](#)). As is well-known, plasticity theory
96 can be employed for collapse load calculation, whereas elasticity theory is usually
97 used to predict strain or displacement. Limit equilibrium approach is efficient for
98 determination of passive pressure coefficients for retaining walls ([Patki et al. 2015](#)).
99 Numerical study by [Potts and Fourie \(1986\)](#) showed that the effect of Young's
100 modulus distribution on the overall stability of a conventional retaining wall
101 (characterized with passive or active pressure coefficients) appears to be negligible.

102 Force-resultant plasticity models for the combined vertical and horizontal
103 loading conditions have been successively developed and employed for simulating
104 the pipeline on-bottom responses (e.g., [Zhang et al. 2002](#); [Hodder and Cassidy 2010](#)).
105 These numerical models were based on the plasticity theory and verified by series of

106 sideswipe tests of a partially embedded pipeline on calcareous sands. The behaviors
107 of the entire pipe foundation were encapsulated by relating the resultant forces to the
108 corresponding displacements of the pipeline.

109 The previous numerical and the empirical analyses were mainly for the
110 condition of horizontally flat seabed, which is typical for the shallow continental
111 shelf regions. As the offshore engineering practice moving to the deeper continental
112 slope regions, the influence of the seabed slope should be taken into consideration
113 for evaluating the ultimate lateral-resistance of the submarine pipelines. In the
114 existing theoretical investigations on the pipeline lateral stability, the influence of the
115 slope angle of the seabed has not been considered yet.

116 In this study, an improved analytical pipe-soil interaction model is developed on
117 the basis of the passive soil pressure theory to assess the lateral instability of
118 submarine pipelines on a sloping sandy seabed. The developed model is verified by
119 the existing experimental and numerical results. The effect of seabed slope angle on
120 the lateral on-bottom stability is further investigated.

121 **Critical Soil Resistance for a Partially-embedded Pipeline**

122 **Assumptions and application scopes**

123 For the pipeline-soil interaction system subject to ocean current loading, a proper
124 evaluation of the soil resistance is key to evaluate the pipeline on-bottom stability,
125 especially when a sloping seabed is encountered. If the hydrodynamic loads are large
126 enough to induce the pipeline instability, the consequence of the lateral pipeline
127 movement is to bring the neighboring soil of the sloping seabed from a quasi- K_0

128 state to a passive limiting equilibrium state. In this analytical investigation, in order
 129 to derive a reasonable analytical solution for evaluating the soil resistance to an
 130 unburied pipeline, the main assumptions and application scopes are discussed and
 131 listed as follows.

132 As the rigidity of a submarine pipeline is normally much larger than that of the
 133 soils, it would be reasonable to assume the pipeline as a rigid shallow foundation. In
 134 the offshore fields, the submarine pipeline diameter (D) normally ranges from
 135 several inches to around 40 inches (~ 1.0 m). The examined embedment-to-diameter
 136 ratio (e_0/D) is in the range of 0 to 0.5. Due to the constraints from the pipeline ends
 137 linking with the subsea well-heads and/or from the locking blocks, the anti-rolling
 138 condition is under consideration, i.e. the pipeline may move in parallel or normal to
 139 the seabed surface, but the free rolling is prohibited.

140 The hydrodynamics on the partially-embedded pipeline under the action of
 141 ocean currents include the drag force F_D (parallel to the seabed surface) and the lift
 142 force F_L (upward perpendicular to the seabed surface) (see Fig. 1), which can be
 143 calculated with the Morison equations (Morison et al. 1950), i.e.

$$144 \quad (2a) \quad F_D = \frac{1}{2} C_D \rho_w D U^2$$

$$145 \quad (2b) \quad F_L = \frac{1}{2} C_L \rho_w D U^2$$

146 where C_D and C_L are the drag and the lift force coefficient, respectively; ρ_w is the
 147 mass density of the water (in kg/m^3); D is the outer diameter of the submarine
 148 pipeline; U is the velocity of the ocean currents (in m/s). As recommended by Jones
 149 (1978), the effective hydrodynamic coefficients (C_D and C_L) for a pipeline resting on

150 the seabed ($e/D = 0$) can be determined with their correlations with the values of
151 Reynolds number ($Re = UD/\nu$ is the ratio of inertia force to viscous force; ν is
152 the kinematic viscosity of water (in m^2/s). $\nu \approx 1.5 \times 10^{-6} \text{ m}^2/\text{s}$ for water at 5°C). With
153 Re increasing from 3.0×10^4 to 1.0×10^6 , both the drag coefficient C_D and the lift
154 coefficient C_L decrease gradually to constant values with similar trends (also see [Gao
155 et al. 2011](#)).

156 The above Morison equations with the modification of drag and lift coefficients
157 by [Jones \(1978\)](#) may provide a convenient approach for the pipeline hydrodynamics
158 calculation. Such a conventional calculation approach is semi-empirical, in which
159 the force coefficients were determined from the tests. [Soedigdo et al. \(1999\)](#)
160 proposed a more sophisticated analytical model (i.e. Wake II model) for predicting
161 the near-wall pipeline hydrodynamics in waves, in which the wake velocity
162 correction was derived based on a closed-form solution to the linearized Navier–
163 Stokes model for oscillatory flow and the hydrodynamic forces coefficients were
164 determined based on start-up effects. Note that in those models for hydrodynamic
165 loads calculations, the penetration effect has not been taken into account. It was
166 observed by [Jacobsen et al. \(1989\)](#) that while the pipeline partially penetrating into
167 the seabed, the hydrodynamic loads are decreased gradually, noting that the lift
168 coefficient is influenced slightly when the embedment-to-diameter ratio is less than
169 0.10. The recommended reduction factors due to pipeline penetration/embedment for
170 the hydrodynamic loads can be referenced in [Det Norske Veritas \(2010\)](#).

171 For the current-induced pipeline on-bottom stability on the sloping seabed with

172 a slope angle (α), the following force equilibrium equations should be satisfied in
 173 both directions of parallel (x) and perpendicular (y) to the seabed surface,
 174 respectively (Fig. 1):

$$175 \quad (3a) \quad F_R = F_D - W_s \sin \alpha \quad (\text{in } x \text{ direction})$$

$$176 \quad (3b) \quad F_C = W_s \cos \alpha - F_L \quad (\text{in } y \text{ direction})$$

177 where F_C is the prop force of the seabed to the unburied pipeline, i.e. the net normal
 178 load in between the pipeline and the underlying soil.

179 The sandy seabed is taken into account in this analytical investigation. Sand
 180 sediments can be deposited at different rates, resulting in a range of initial densities
 181 which influence subsequent behaviors (Potts and Zdravkovic 1999). As a shallow
 182 foundation, the partially-embedded pipeline can be supposed as a retaining structure.
 183 While losing lateral stability, the pipeline pushing the frontal sand ahead can be
 184 regarded as a quasi-static process, where a fully drained condition is basically
 185 satisfied in the shallow sand layer.

186 A two-dimensional (2-D) plane strain elasto-plastic Finite Element (FE) model
 187 was recently proposed by Han (2012) to predict the pipeline-soil interaction behavior
 188 on the sloping seabed. A series of FE analyses (Han, 2012) indicated that the plastic
 189 failure zone developed in the proximity of the pipeline when losing lateral stability is
 190 quite similar to that in the previous analyses on the retaining walls (Potts and
 191 Zdravkovic 2001). The details for the typical numerical simulation can be seen in the
 192 latter section for the model validation. This can also provide a reasonable
 193 confirmation of the empirical pipe-soil interaction model based on the test

194 observations by [Wagner et al. \(1989\)](#), i.e. the total soil resistance includes the
195 sliding-friction and the passive-pressure components.

196 The submarine slopes are always encountered in the offshore pipeline
197 engineering, which are generally gentler than the typical slopes on land. In this study,
198 the influence of slope angle on the pipeline on-bottom instability is examined
199 analytically with the proposed model. Two typical on-bottom instabilities are
200 involved, i.e. (1) Type-I: downslope instability and (2) Type-II: upslope instability.
201 The effects of slope angle will be investigated in the later section.

202 Based on the aforementioned analyses and discussions, in the proposed
203 analytical model, the composite failure surface comprises a sliding-friction segment
204 and a passive-pressure segment. The passive pressure is to be calculated with the
205 well-known Coulomb's theory of passive earth pressure for the soil slopes at a
206 constant angle to the horizontal ([see Craig 2004; Chen and Liu 1990](#)). In this study,
207 the examined absolute values of the slope angle are in the range of $0\sim 15^{\circ}$, which
208 covers the common submarine in-situ conditions.

209 In this theoretical derivation, the plane-strain condition is under consideration,
210 i.e. the pipeline is aligned with the bathymetric contours of the sloping seabed, and
211 the current is flowing perpendicularly to the pipeline. For more general cases with
212 oblique flow and run-off elevation laying, the conditions would be three-dimensional
213 in nature and the axial flow-pipe-soil interaction effects would emerge, for which the
214 present theoretical solutions could not be extended directly and should be further
215 examined.

216 **Derivation**

217 As previously stated, the Coulomb's theory of passive earth pressure is incorporated
 218 in the present analytical model. The composite failure surface for the lateral pipe-soil
 219 interaction on a sloping seabed (see Fig. 2 and Fig. 3) includes a sliding-friction
 220 segment (denoted as "segment-DB") and a passive-pressure segment
 221 ("segment-BC"). Fig. 2 and Fig. 3 illustrate the geometry of failure mechanism and
 222 the force triangles for the downslope instability and those for the upslope instability,
 223 respectively. Along both segments (segment-DB and segment-BC), the shear
 224 strength of the soil is fully mobilized while the pipeline losing lateral stability.

225
 226 **Fig. 2. Downslope instability of a submarine pipeline: (a) Geometry of failure**
 227 **mechanism; (b) Triangle of the forces on the wedge-ABD (shaded area in Fig**
 228 **2(a))**

229 **Fig. 3. Upslope instability of a submarine pipeline: (a) Geometry of failure**
 230 **mechanism; (b) Triangle of the forces on the wedge-ABD (shaded area in Fig**
 231 **3(a))**

232
 233 Based on the Coulomb's theory of passive earth pressure, the shearing
 234 resistance on the segment-BC and the weight of the wedge-ABC would be balanced
 235 by the thrust force (E_1) on a virtual retaining wall-AB. The length of the virtual
 236 retaining wall-AB has the same value with the pipeline embedment (e_0). As
 237 illustrated in Fig. 2(a) and Fig. 3(a), the retaining wall-AB is supposed perpendicular

238 to the seabed surface, and the sliding-friction segment-DB is parallel to the seabed
 239 surface (i.e. perpendicular to the wall-AB).

240 Choosing the wedge-ABD (the shaded areas in Fig. 2(a) and Fig. 3(a)) as the
 241 analysis object, the main forces acting on the wedge-ABD at failure for these two
 242 types of instabilities include: (1) The passive earth pressure on the virtual retaining
 243 wall-AB, the total force of which, as stated above, is denoted as the thrust force E_1 ;
 244 (2) The sliding-friction force (E_2) on the segment-DB, with an inclination angle (φ)
 245 to the normal; (3) The submerged weight of the wedge-ABD; and (4) The total
 246 pipe-soil interfacial force (P). The details of the calculation for these forces are as
 247 follows.

248 The passive earth pressure E_1 can be calculated with Coulomb's theory of
 249 passive earth pressure for the soil surface slopes (see Craig 2004):

$$250 \quad (4) \quad E_1 = \frac{1}{2} \gamma' (e_0 \cos \alpha)^2 K_p$$

251 where " $e_0 \cos \alpha$ " is the vertical component of the length of the wall-AB (see Fig. 2(a)
 252 or Fig. 3(a)); K_p is the passive pressure coefficient for the sloping soil with a
 253 constant slope angle (α):

$$254 \quad (5) \quad K_p = \left[\frac{\cos(\varphi + \alpha') / \cos(\alpha')}{\sqrt{\cos(\varphi' - \alpha') - \sqrt{\sin(\varphi + \varphi') \sin(\varphi + \alpha) / \cos(\alpha - \alpha')}}} \right]^2$$

255 in which, the internal friction angle of the sand (φ) is the drained (effective stress)
 256 shear strength parameter for the sand; α' is the angle between the virtual retaining
 257 wall-AB and the vertical; φ' is the mobilized friction angle at the wall-AB. As for a
 258 sloping seabed with slope angle α , the virtual retaining wall-AB is supposed to be

259 inclined with an inclination angle α' . Both angles (α and α') are included in the
 260 expression of K_p by eq. (5). Considering the examined values of α' range from
 261 $-15^\circ \sim 15^\circ$, the values of α' can be regarded as the same with the slope angle α for
 262 the purpose of simplification in the derivation. The friction angle along the retaining
 263 wall (φ') is always partially mobilized, whose values in the passive case are usually
 264 less than $\varphi/3$ (Craig 2004). As such, choosing the value of φ' as nil would be
 265 conservative for evaluating the lateral soil resistance to the partially-embedded
 266 pipeline. Submitting $\alpha'=\alpha$ and $\varphi' \approx 0$ into eq. (5), then

$$267 \quad (6) \quad K_p = \left[\frac{\cos(\varphi + \alpha) / \cos(\alpha)}{\sqrt{\cos(\alpha) - \sin(\varphi) \sin(\varphi + \alpha)}} \right]^2$$

268 Fig. 4 gives the variation of values of the passive pressure coefficient (K_p) with the
 269 slope angle (α) for certain values of the internal friction angle of the sand ($\varphi = 25^\circ$,
 270 30° , 35° , 40° and 45°). Note that the values of α are positive for the upslope
 271 instability, whereas they are negative for the downslope instability. When $\alpha = 0$
 272 (meanwhile $\varphi' = 0$), the passive pressure coefficient (K_p) in the Coulomb theory (eq.
 273 (6)) is identical to that of the Rankine theory for the case of a vertical wall and a
 274 horizontal soil surface, i.e. $K_p = (1 + \sin \varphi) / (1 - \sin \varphi)$. As shown in Fig. 4, for a certain
 275 value of φ , the values of K_p increase gradually with increasing slope angle α (from
 276 -15° to 15°). Meanwhile, if the values of α is fixed, the K_p increases gradually with
 277 the increase of φ .

278

279 **Fig. 4. Variation of the passive pressure coefficient (K_p) with the slope angle**

280 (α)

281 The submerged weight of the wedge-ABD (i.e. the shaded areas in Fig. 2(a) and
 282 Fig. 3(a)) can be calculated with

$$283 \quad (7) \quad W_b = \frac{\gamma'}{8} \left[4e_0^2 \frac{1 + \cos \theta_0}{\sin \theta_0} - D^2 (\theta_0 - \sin \theta_0) \right]$$

284 in which, $\theta_0 (= \angle AOD)$, see Fig. 2(a) or Fig 3(a)) is a half of the angle of the
 285 pipeline penetration:

$$286 \quad (8) \quad \theta_0 = \arccos \left(1 - 2 \frac{e_0}{D} \right)$$

287 It should be noticed that the pipe-soil interface is the circular arc-AD (Fig. 2(a)
 288 and Fig. 3(a)). For a better description for the loading angle of the total pipe-soil
 289 interfacial force (P), the circular arc-AD is simplified as the straight line segment
 290 AD', i.e. the diagonal-line for the secant and the tangent lines from point-A of the
 291 pipe-soil contacting circular arc-AD. This simplification treatment was approved
 292 appropriate by a series of calculation trials. The angle $\angle D'AB$ (termed as “ β ”) is
 293 the intersection angle between the virtual retaining wall-AB and the line segment
 294 AD'. If the value of θ_0 is given, the value of β can be calculated with

$$295 \quad (9) \quad \beta = \frac{\pi}{2} - \frac{3}{4} \theta_0$$

296 Once the geometry of the proposed model is provided as described above, the
 297 total pipe-soil interfacial force (P) can thereby be derived following the analysis on
 298 the forces on the wedge-ABD (Fig. 2 and Fig 3). By using the “law of sines” to the
 299 triangle of forces ($\triangle LMN$):

300 (10)
$$\frac{P}{\sin(\angle MNL)} = \frac{F_{MN}}{\sin(\angle MLN)}$$

301 in which, $\angle MNL = \pi/2 + \omega + \varphi$; $\angle MLN (= \pi/2 - (\beta - \delta) - \varphi) = 3\theta_0/4 + \delta - \varphi$;

302 F_{MN} is the resultant force of E_1 and W_b : $F_{MN} = (E_1 \cos \varphi' + W_b \sin \alpha) / \cos \omega$. Thus,

303 the total pipe-soil interfacial force P can be obtained:

304 (11)
$$P = \frac{\cos(\varphi + \omega)}{\cos(\omega) \sin(3\theta_0/4 + \delta - \varphi)} (E_1 \cos \varphi' + W_b \sin \alpha)$$

305 where δ is the inclination angle to the normal for P . Note that the signals of δ are

306 positive for the clockwise of the P in the case of downslope instability (Fig. 2(a))

307 and for the anti-clockwise of the P in case of upslope instability (Fig. 3(a)),

308 respectively. ω is the intersection angle between the direction of F_{MN} to the

309 seabed surface (Fig. 2(b) and Fig 3(b)), which can be calculated by

310 (12)
$$\omega = \arctan \left(\frac{E_1 \sin \varphi' - W_b \cos \alpha}{E_1 \cos \varphi' + W_b \sin \alpha} \right)$$

311 When the friction angle along the retaining wall-AB approaching zero, i.e. the thrust

312 force E_1 is acting approximately normally to the retaining wall, eq. (12) can then be

313 expressed as

314 (12')
$$\omega \approx \arctan \left(\frac{-W_b \cos \alpha}{E_1 + W_b \sin \alpha} \right) \quad (\text{for } \varphi' \approx 0)$$

315 Once the total pipe-soil interfacial force (P) is predicted by eq. (11), the critical

316 (maximum) lateral soil resistance (F_R) and the corresponding prop force (F_C) for

317 the pipeline instability on the sloping seabed can be further obtained:

318 (13a)
$$F_R = P \cos(\beta - \delta)$$

319 (13b)
$$F_C = P \sin(\beta - \delta)$$

320 The force equilibrium conditions (eqs. (3a) and (3b)) are utilized to identify the
 321 unique failure surface by solving these equation group. Submitting eqs. (13a) and
 322 (13b) into the force equilibrium equations eqs. (3a) and (3b), then

$$323 \quad (14) \quad \tan(\beta - \delta) = \frac{W_s \cos \alpha - F_L}{F_D - W_s \sin \alpha}$$

324 Furthermore, submitting eq. (9) into eq. (14), the geometry relationship between the
 325 pipeline penetration and the direction for total pipe-soil interfacial force can be
 326 established:

$$327 \quad (15) \quad \frac{3}{4}\theta_0 + \delta = \arctan\left(\frac{F_D - W_s \sin \alpha}{W_s \cos \alpha - F_L}\right)$$

328 If the values of the following parameters for the soil and the pipeline are known,
 329 i.e. α , φ , D , γ' , W_s and U , then the two unknown values of θ_0 and δ can be
 330 determined by eq. (15) together with one of the two eqs. (3a) and (3b). When the
 331 value of θ_0 is obtained, the pipeline embedment (e_0) can be further calculated by eq.
 332 (8). In the engineering practice, this calculated value of e_0 could be treated as the
 333 critical (minimum) pipeline embedment for on-bottom stability (termed as “ e_{cr} ”).

334 Similar to the above ‘scene representation’, if the value of the pipeline
 335 embedment (e_0) is given (W_s is not known in advance), the values of W_s together
 336 with δ can also be determined by solving the same equation group, i.e. eqs. (15)
 337 and (3a) or (3b).

338 Note that the signals of δ can be either positive or negative. Nevertheless, the
 339 absolute values of the pipe-soil interfacial friction angle ($|\delta|$) should be no larger
 340 than its critical value (δ_{crit}), i.e. $|\delta| \leq \delta_{crit}$; Otherwise, the partially-embedded

341 pipeline would breakout from its in-place location through the pipe-soil interfacial
 342 slippage. In accordance with classical plasticity theory, the critical pipe-soil
 343 interfacial friction angle can be evaluated with

$$344 \quad (16) \quad \delta_{\text{crit}} = \arctan \left(\frac{\sin \varphi \cos \nu}{1 - \sin \varphi \sin \nu} \right)$$

345 in which, ν is the angle of soil dilation. Eq. (16) is a direct consequence of the
 346 assumption of coincidence of stress and the plastic strain increment directions, and
 347 that the soil is plastic immediately adjacent to the wall (pipe-soil interface) (Potts and
 348 Fourie 1986; Lee and Herington 1972).

349 **Three components of the critical soil resistance**

350 As aforementioned, in the pipe-soil interaction model (Wagner et al. 1989), the
 351 lateral resistance F_R to the submarine pipeline on a horizontal sandy seabed ($\alpha = 0$)
 352 was evaluated by the form of eq. (1). As discussed in the introduction, their model is
 353 essentially empirical, with high uncertainty in the empirical coefficient β_0 for
 354 evaluating the passive pressure. Unlike the previous model, the present pipe-soil
 355 interaction model for a sloping sandy seabed may provide an explicit expression of
 356 the three components of the critical lateral soil resistance (Figs. 3(b) and 4(b)):

$$357 \quad (17) \quad F_R = \underbrace{0.5\gamma'(e_0 \cos \alpha)^2 \cos(\varphi')}_{F_{Rp}} K_p + \underbrace{E_2 \sin \varphi}_{F_{Rf}} + \underbrace{W_b \sin \alpha}_{F_{Rw}}$$

358 in which F_{Rp} , F_{Rf} and F_{Rw} are the passive-pressure, the sliding-friction, and the
 359 additional submerged weight (from the wedge-ABD) components, respectively; K_p
 360 and W_b can be calculate by eq. (6) and eq. (7), respectively; the total sliding-friction
 361 E_2 along the bottom of the wedge-ABD (Figs. 2(a) and 3(a)) can be calculated in

362 accordance with the law of sines for the forces of triangle (ΔLMN ; see Fig. 2(b) and
 363 3(b)):

$$364 \quad \frac{F_{MN}}{\sin \angle MLN} = \frac{E_2}{\sin \angle LMN}, \text{ i.e. } \frac{(E_1 \cos \varphi' + W_b \sin \alpha) / \cos \omega}{\sin(\pi/2 + \delta - \beta - \varphi)} = \frac{E_2}{\sin(\beta - \delta - \omega)}.$$

365 Thus, the total sliding-friction E_2 can be expressed as

$$366 \quad (18) \quad E_2 = \frac{\sin(\beta - \delta - \omega)}{\cos(\omega) \cos(\beta - \delta + \varphi)} (E_1 \cos \varphi' + W_b \sin \alpha)$$

367 In the following sections, the verification and mechanism analysis will be made
 368 on the pipe-soil interaction, in which the force components of the critical soil
 369 resistance will be presented in detail.

370 **Verification of the Proposed Model**

371 The proposed pipe-soil interaction model is verified with the existing results of a
 372 series of full scale tests by Wagner et al. (1989). Table 1 gives the detailed
 373 comparisons between the existing test results and the predictions with the present
 374 model for pipe-soil interactions on flat sand-beds.

375 Table 1 lists the results of 10 series of pipe-soil interaction tests on a loose
 376 medium/coarse sand, and 5 series of tests on dense medium/coarse sand for the
 377 comparison with the predicted values. In the reference (Wagner et al. 1989), the
 378 information on the internal friction angle (φ) was not provided, but values of the
 379 relative density for the test sands were given. As listed in Table 1, the values of φ
 380 are evaluated by considering the concept of relative dilatancy index (Bolton 1986),
 381 i.e. for a plane strain problem:

382 (19)
$$\varphi \approx \varphi_{\text{crit}} + 5I_{\text{R}}$$

383 where φ_{crit} is the critical state angle of shearing resistance of sands (the
 384 recommended $\varphi_{\text{crit}} = 35^\circ$ for quartz sands); I_{R} is the relative dilatancy index:
 385 $I_{\text{R}} = D_{\text{r}}(10 - \ln p') - 1$, in which D_{r} is the relative density of sands, p' is the
 386 mean effective stress (in kPa). In addition, those pipe-soil interaction tests mainly
 387 involved monotonic and cyclic loadings. Note that in their cyclic loading tests, the
 388 oscillations were applied in advance, which were only to obtain the additional pipe
 389 penetration. In the table, e_{cr}/D refers to the ratio of the total embedment (including
 390 initial embedment and additional penetration) to the pipe diameter. The breakout
 391 loads was measured to obtain the values of F_{R} ($=F_{\text{D}}$ for the case of horizontal
 392 seabed). The values of " $W_{\text{s}} - F_{\text{L}}$ " are the net vertical prop loads between the pipe and
 393 the underlying sand.

394 As aforementioned, if the parameters for the sand and the pipeline (i.e. φ , D ,
 395 γ' , W_{s} , F_{D} and F_{L}) are given, the critical value of θ_0 for the pipeline losing
 396 on-bottom stability can be determined by eq. (15) and one of the two eqs. (3a) and
 397 (3b). When the value of θ_0 is obtained, the corresponding critical pipeline
 398 embedment ratio (e_{cr}/D) can be calculated by eq. (8). With present model, the
 399 passive-pressure and sliding-friction components (F_{Rp} and F_{Rf}) of the total lateral
 400 soil resistance (F_{R}) can be easily identified and calculated by eq. (17). The predicted
 401 values of F_{Rp} and F_{Rf} are also listed in the right two columns in Table 1.

402 Fig 5 gives the comparison of the predicted critical pipeline
 403 embedment-to-diameter ratio with the experimental results. The comparison

404 indicates that the predictions by the present model and the measured values by
405 [Wagner et al. \(1989\)](#) are generally in good agreement. As shown in [Fig. 5](#), there
406 exists some scattering in the data for the conditions of shallow embedment or light
407 submerged weight of pipelines (see [Table 1](#)), where the passive-pressure
408 component is less dominant compared to the contributions from the sliding-friction
409 mechanism. Except for those shallow embedments, the predictions are in general
410 larger than the experimental results ([Fig. 5](#)), which may be attributed to that the
411 effect of soil heave was not taken into account in the present model. This may imply
412 the proposed model would be somewhat conservative for predicting the soil lateral
413 resistance.

414 An alternative approach is performed by finite element analysis (FEA) to study
415 the soil-structure interaction ([Potts and Fourie 1986](#)). As stated in the previous
416 section, a 2-D plane strain elasto-plastic FE model proposed by [Han \(2012\)](#) was
417 employed for predicting the pipeline-soil interaction behavior on the sloping seabed.
418 [Fig. 6](#) shows the FE results of the case study for the plastic zones around
419 partially-embedded pipelines while losing lateral instability on a sloping sand-bed
420 ($D=0.5\text{m}$, $e_0/D=0.2$, $W_s=1.568\text{ kN/m}$, $\mu=0.3$, $\varphi=30^\circ$). As illustrated in [Fig. 6](#),
421 for both the downslope instability ($\alpha=-10^\circ$) and the upslope instability ($\alpha=10^\circ$),
422 the plastic yielding zones that developed in the proximity of the partially-embedded
423 pipeline hold typical characteristics of retaining structures. It was observed that the
424 plastic yielding zones were close to the pipeline bottom and protruded gradually to
425 the soil surface. The passive failure was clearly identified by the plastic strain

426 development in these plots. Such observations (Figs. 6(a) and 6(b)) in the numerical
 427 modeling facilitate the construction of the failure modes (Figs. 2(a) and 3(a)) in the
 428 present analyses.

429
 430 **Table 1. Test results by Wagner et al. (1989) and predictions with the**
 431 **present model for pipe-soil interactions on flat sand-beds.**

432 **Fig. 5. Comparison of the predicted critical pipeline embedment (e_c/D) with the**
 433 **experimental results**

434 **Fig. 6. FE results of plastic zones around partially-embedded pipelines while**
 435 **losing lateral instability on a sloping sand-bed ($D=0.5\text{m}$, $e_0/D=0.2$, $W_s=1.568$**
 436 **kN/m, $\varphi=30^\circ$): (a) Downslope instability ($\alpha=-10^\circ$); (b) Upslope instability (α**
 437 **$=10^\circ$)**

438 It should be noticed that the instability of a submarine pipeline under the action
 439 of waves or currents is frequently accompanied by local scour or liquefaction of the
 440 soil (Gao et al. 2002; Teh et al. 2003; Gao et al. 2007). As previously pointed by
 441 Palmer (1996), the sediment transport of the seabed surface layer can be significant
 442 under the extreme conditions in the offshore fields. There exists a non-linear
 443 relationship between the non-dimensional critical flow velocity (Shields number)
 444 and the particle diameter of the sediments (Chien and Wan, 1999). Therefore, in the
 445 pipe-soil interaction analysis, the seabed mobility should be well evaluated
 446 simultaneously. When the seabed mobility is not predominant, the proposed pipe-soil
 447 model can be employed for a satisfactory prediction of the soil resistance.

448 **Effects of Slope Angle**

449 As aforementioned, the sloping seabed is encountered more frequently in deeper
450 waters. The seabed in the South China Sea holds rich varieties of its topographic
451 feature including the vast continental shelf, the continental slope and deep sea basin.
452 The seabed slope angle changes much at various locations, e.g., the measured slope
453 angle generally reaches up to 6.7-17.6 degree at the western continental slope of
454 South China Sea (Liu et al. 2002). To investigate the influence of slope angle on the
455 pipeline lateral instability on a sloping seabed, a case study is performed by using
456 the proposed pipe-soil interaction model.

457 **Table 2** gives the input parameters of the pipeline, the sand and the ocean
458 current. The examined slope angle (α) is in the range of -15° ~ 15° . Given the value of
459 φ and the α range, the variation of passive pressure coefficients can be calculated by
460 eq. (6). As aforementioned, if the values of the parameters listed in **Table 2** are
461 known, the values of the critical pipeline embedment (e_{cr}) could be predicted using
462 the proposed model.

463 The predicted results are shown in **Figs. 7(a) and 7(b)**. It is indicated in **Fig. 7(a)**
464 that the values of e_{cr} (and e_{cr}/D) decreases approximately linearly with the increase in
465 slope angle (α from -15° to 15°). **Fig. 7(b)** illustrates the variations of the total soil
466 resistance (F_R) and its three components (F_{Rp} , F_{Rf} and F_{Rw}) with the slope angle. It
467 could be found in this figure that, the sliding-friction component F_{Rf} and the
468 submerged weight component F_{Rw} change slightly with the variation of the slope
469 angle. Nevertheless, the passive-pressure component F_{Rp} decreases approximately

470 linearly with increasing the slope angle, which is accompanied by the significant
 471 decrease in the critical embedment. This implies that to keep the submarine pipeline
 472 stable under the action of a downslope current, a larger value of pipe embedment (e_{cr})
 473 is needed to avoid the occurrence of downslope instability, where a higher
 474 passive-pressure (F_{Rp}) could be mobilized to obtain the required soil resistance.

475

481

482 **Conclusions**

483 As the offshore exploitation shifting from shallow to deep waters, the ocean current
 484 would exert the prevailing hydrodynamics on the submarine pipeline. Meanwhile,
 485 the sloping seabed would be encountered frequently, especially at the continental
 486 slopes. In this study, the ocean current-induced on-bottom stability of a submarine
 487 pipeline laid on a sloping sandy seabed is investigated analytically. The main
 488 conclusions drawn from this analysis are as follows:

- 489 1. Unlike the previous pipe-soil interaction models for the horizontal seabed
 490 conditions, a pipe-soil interaction model is proposed for evaluating the lateral
 491 soil resistance to a partially-embedded pipeline on a sloping sandy seabed. The

492 mechanics for the two types of the current-induced pipeline instability are
493 analyzed, i.e. the downslope instability and the upslope instability.

494 2. By using limit equilibrium approach, the analytical expression of the total lateral
495 soil resistance are derived, which is composed of the sliding-friction component,
496 the passive-pressure component, and the component of submerged weight of the
497 carried soil wedge. The Coulomb's theory of passive earth pressure for the
498 sloping soil is incorporated in the derivation. The model verification with the
499 existing full scale tests shows a good agreement between the experimental
500 results and the predictions.

501 3. Parametric study indicates that the effect of slope angle on the pipeline lateral
502 soil resistance is significant in the examined range of the slope angle from -15° to
503 15° . The critical pipeline embedment and the corresponding passive-pressure
504 decreases approximately linearly with increasing slope angle.

Submerged weight of the pipeline W_s (kN/m)	0.75	
Effective unit weight of the sands γ' (kN/m ³)	9.6	
Internal friction angle of the sands φ (°)	35°	
Examined range of slope angle α (°)	-15°~15°	
Variation of passive pressure coefficients K_p	3.25~4.33	Fig. 4
