# **1. Introduction**

In recent decades, the scramjet has received extensive attention as one of the most promising engines for hypersonic vehicles. Due to its superiority in specific impulse, the scramjet shows excellent potential for long-range yet fast civil transport and repeatable round-trip flight for space exploration [\[1\]](#page-11-0). Ground testing for scramjet operating at high Mach flight conditions is challenging, and it is usually hard to achieve a long-period test. Moreover, considering the extremely high cost and the limited available measurement techniques, the flight experiments are unsuitable during the design stage of a scramjet. High-fidelity Computational Fluid Dynamics (CFD) modeling that can simulate extreme flight conditions is becoming one of the indispensable approaches in the fundamental study and concept design of scramjet engines [\[2-4\]](#page-11-0).

However, resolving supersonic combustion is usually challenging because of the complex physics and the formidable computational cost [\[5\].](#page-11-0) Typically, there are strong shock waves and their complex interactions with other flow patterns, such as boundary layer [\[6\],](#page-11-0) shear layer [\[7,8\],](#page-11-0) and vortexes [\[9\].](#page-11-0) Under such complex distortions, the modes of turbulence-chemistry interaction become highly heterogeneous and evolve rapidly in the combustor [\[10-12\]](#page-11-0). As a result, the combustion in scramjet engines is inherently unstable and contains a broad range of characteristic time and length scales, raising significant challenges for its modeling [\[13-15\].](#page-11-0) High-fidelity numerical methods, such as large

eddy simulation (LES) or direct numerical simulation (DNS), are necessary to accurately capture the details of the combustion process and reveal the instability mechanism and mode transition of the supersonic combustion [\[16-18\]](#page-11-0). However, in practical combustor design, LES simulations on grids with tens or hundreds of millions of cells undoubtedly require huge computational costs, especially for combustion models involving tens or even hundreds of elementary reactions. It is estimated that the direct integration (DI) of combustion chemistry takes*>*50% of the total modeling time [\[19\]](#page-12-0). There are two main approaches to relieving the computing load of resolving combustion chemistry. One is the direct acceleration methods, including the mechanism reduction techniques, such as DAC [\[20\]](#page-12-0) and ISAT [\[21\]](#page-12-0), and accelerating the direct integration of stiff reaction systems with the aid of GPU acceleration [\[22\]](#page-12-0) or Artificial Neural Network (ANN) [\[23\].](#page-12-0) The alternative approach adopts the moment method based on conserved scalars, such as the variants of flamelet models  $[13,14]$  and the Conditional Moment Closure (CMC) model [\[15,16\]](#page-11-0). The above models reduce the dimension of the manifold of reaction systems by transforming the status of reacting scalars to a distribution function in the multidimensional state space coordinated by the conserved scalars, e.g., mixture fraction and reaction progress variables. Using such models, the computational cost of combustion modeling assuming detailed mechanisms with large numbers of species and stiff reactions can be reasonably and significantly reduced relative to that of the finite-rate models, such as PaSR  $[17]$  and EDC  $[18]$ .

<sup>\*</sup> Corresponding author at: State Key Laboratory of High Temperature Gas Dynamics, Institute of Mechanics, CAS, No. 15 Beisihuanxi Road, Beijing 100190, China. *E-mail address:* [weiyao@imech.ac.cn](mailto:weiyao@imech.ac.cn) (W. Yao).

The closure of nonlinear chemical source terms with high turbulent scalar fluctuations in supersonic combustion [\[24\]](#page-12-0) has not been given sufficient attention by the combustion modeling community. Compared with subsonic combustion, the combustion within the scramjet bears a high-Re turbulent flow, where the Kolmogorov scale of the turbulence is comparable to or smaller than the scale of reaction zones. The penetration of eddies into the flame front strengthens the coupling between turbulence and chemistry. More likely, the structures of the reaction zone within the flame are dominated by turbulent pulsation rather than by molecular diffusion, as in laminar flames [\[1\]](#page-11-0). Therefore, the capability of the flamelet model based on an ensemble of thin laminar flamelets for turbulent supersonic combustion is questionable. The conditional-moment-based models [25–[28\]](#page-12-0) adopt a similar flamelet concept, but the "flamelet" (conditional moment) is constructed based on the conditional averaged species transport equations and mapped in the conditional space. Therefore, their applications are not restricted by the thin flamelet assumption. To accurately close the chemical source term in the conditional space, it is necessary to have small fluctuations of reacting parameters, i.e., the mass fractions of species and enthalpy fluctuate mildly around their conditional means. For subsonic combustion, a first-order closure model based on a single conditional variable (single conditioning) can give good predictions of the experiments [\[29\]](#page-12-0). However, for supersonic combustion, where the turbulence-chemistry interaction (TCI) modes vary significantly in the domain, the single conditioning can not guarantee the first-order closure model's validation due to the weak correlations between the reacting scalars and the single conditioning variable. For this, two specific extensions to the singly-conditioning, first-order moment closure model are developed, i. e., (1) the double-conditioning model [\[30\]](#page-12-0) to reduce the fluctuations of the reacting scalars deviating from the conditional means, especially for the non-premixed and premixed modes coexisting flame [\[31\]](#page-12-0), and (2) the second-order closure [\[32\]](#page-12-0) to directly diminish the error introduced in closing the conditionally averaged source terms. Although those

extended models improve the accuracy in describing spatiotemporally varying TCI modes, they also increase the number of equations to be solved and complicate the closure of conditionally averaged terms, especially the higher-order moments, which still lack sufficient verification from experiments or DNS data [\[33\]](#page-12-0). For the LES simulations implemented with detailed reaction mechanisms, using a doubleconditioning or second-order moment model will significantly increase the computational cost and complexity, which is not suitable for applications in practical combustion devices.

Following the concept of a flamelet-like model based on the conditional moment, a zonal flamelet model has been proposed recently [\[34\]](#page-12-0). To reduce the conditional fluctuations, a zone division strategy is used by assuming that species and temperature fluctuations within each zone can be controlled to be small around the local conditional means. The zone is divided by flow variables rather than solely by coordinates, and therefore the TCI modes of the cells contained within each zone can be controlled to be similar by properly selecting the zone division indices. The dynamical zoning method weakens the statistical dependence of the local reacting states on space other than that which are embedded in the conditioning variables and realizes a strong correlation between the single conditioning scalar (e.g., mixture fraction) and conditioned reacting scalars, i.e., an accurate representation of the local reacting state by the zonal flamelet (the local distribution of conditional moments in the conditional space with each zone). Through dynamically updating the zone division to maintain a low conditional fluctuation level within each zone, the traditional singly-conditioning, first-order moment closure model becomes applicable for highly transient and high-Re supersonic combustion [\[35,36\]](#page-12-0).

In this study, the dynamic zone flamelet model (DZFM) is coupled with the Improved Delayed Detached Eddy Simulation (IDDES) to achieve efficient yet accurate modeling of a model scramjet of DLR [\[37\]](#page-12-0), which has been numerical investigated using flamelet  $[3,38]$  or finiterate [\[38-40\]](#page-12-0) models due to its abundant experimental data [\[37,41\]](#page-12-0). <span id="page-2-0"></span>This study aims to verify the capability of DZFM in supersonic combustion with the challenge of various flame modes ranging from diffusion to premixed and complex turbulent-chemistry interaction (TCI) and to present a modification to DZFM in the low-Re condition. The numerical results are compared with the measured data, and the mixingrelevant flow structures, flame modes, and turbulence-chemistry interaction (TCI) modes in the DLR model combustor are analyzed to validate the capability of DZFM. Finally, the necessity of a low-Re modification to DZFM even for supersonic combustion is demonstrated.

#### **2. Physical model and numerical method**

#### *2.1. Governing equations and turbulent model*

The unsteady and three-dimensional compressible reactive Navier-Stokes equations are solved. All variables  $(\rho, u_i, H_t, Y_\alpha, \tilde{\xi})$  are decomposed into resolved Favre-average quantities  $\tilde{f}$  and unresolved components  $f'$  by a spatial filter in LES. The Favre-averaged equations for the transport of mass, momentum, energy, and species are given as follows,

$$
\frac{\partial \overline{\rho}}{\partial t} + \frac{\partial \overline{\rho} \widetilde{u}_j}{\partial x_j} = 0 \tag{1}
$$

$$
\frac{\partial \overline{\rho} \widetilde{u}_i}{\partial t} + \frac{\partial \overline{\rho} \widetilde{u}_j \widetilde{u}_i}{\partial x_j} + \frac{\partial \overline{p}}{\partial x_i} - \frac{\partial \widetilde{\tau}_{ij}}{\partial x_j} = -\frac{\partial \tau_{ij}}{\partial x_j}
$$
(2)

$$
\frac{\partial \overline{\rho} \widetilde{H}_t}{\partial t} + \frac{\partial \overline{\rho} \widetilde{u}_j \widetilde{H}_t}{\partial x_j} - \frac{\partial}{\partial x_j} \left( \overline{\rho} D_T \frac{\partial \widetilde{H}_t}{\partial x_j} + \sum_{\alpha=1}^L \overline{\rho} D_\alpha \frac{\partial \widetilde{Y}_\alpha}{\partial x_j} \widetilde{H}_\alpha \right) - \frac{\partial \overline{p}}{\partial t} - \frac{\partial \widetilde{u}_j \widetilde{\tau}_{ij}}{\partial x_j} = -\frac{\partial \Psi_{T,j}}{\partial x_j}
$$
(3)

$$
\frac{\partial \overline{\rho} \tilde{\xi}}{\partial t} + \frac{\partial \overline{\rho} \tilde{u}_j \tilde{\xi}}{\partial x_j} - \frac{\partial}{\partial x_j} \left( \overline{\rho} D_a \frac{\partial \tilde{\xi}}{\partial x_j} \right) = - \frac{\partial \Psi_{\xi j}}{\partial x_j}
$$
(4)

$$
\widetilde{\xi^{\prime 2}} = C_{var} \Delta_{sgs} \left| \nabla \widetilde{\xi} \right|^2 \tag{5}
$$

$$
\widetilde{H}_t = \widetilde{H} + \frac{1}{2} \widetilde{u}_t \widetilde{u}_t \tag{6}
$$

$$
\overline{p} = \overline{\rho}R\widetilde{T} \tag{7}
$$

here *t* denotes the time,  $x_i$  and  $u_i$  are the Cartesian coordinate and velocity component in the  $i_{\text{th}}$  direction, respectively,  $\bar{\rho}$  is the average density and  $\bar{p}$  is the average pressure,  $H_t$  is the total absolute enthalpy as the sum of the absolute enthalpy and the kinetic energy.  $\tilde{Y}_a$  is the mass fraction of the species  $\alpha$ ,  $D_T$  is the thermal diffusivity of the mixture, and  $D_{\alpha}$  is the mixture-averaged mass diffusivity of the species  $\alpha$ .  $\widetilde{\xi}$  and  $\widetilde{\xi^{'2}}$  are the mixture fraction and its variance, a constant parameter $C_{var} = 0.1$  is suggested in ref. [\[42\]](#page-12-0) and  $\Delta_{sgs}$  is the filter width for subgrid.  $R = R_u/W$ is the gas constant determined by the molar weight of the mixture *W*, the universal gas constant  $R_u = 8.314 \text{ J/(mol} \bullet \text{K)}.$ 

To correctly resolve the boundary layer with an affordable mesh scale, Improved Delayed Detached Eddy Simulation (IDDES) [\[43\]](#page-12-0) is applied, which models the wall boundary layer and the central flow regions with the one-equation Spalart-Allmaras RANS model and LES model, respectively [\[44\].](#page-12-0) The details of the turbulent model can be found in our previous study  $[35]$ . The chemistry of hydrogen-air combustion is solved based on the detailed mechanism developed for supersonic combustion by Jachimowski [\[45\]](#page-12-0). The thermodynamic and transport properties of the gas mixture are calculated using the chemical kinetics package-II [\[46\]](#page-12-0) based on the NIST-JANAF thermochemical database [\[47\]](#page-12-0) and a CHEMKIN-format transport database. The viscosity, specific heat, and conductivity are all assumed only depend on temperature. The mixture-averaged viscosity and thermal conductivity are

calculated using the modified Wilke's law [\[48\]](#page-12-0) and the combination averaging, respectively. Mixture-averaged mass diffusivities are calcu-lated by Bird's formula [\[49\]](#page-12-0), where the mass conservation is achieved by setting the nitrogen as the inert gas.

# *2.2. Turbulent combustion model*

The dynamic zone flamelet model (DZFM) [\[35\],](#page-12-0) which is based on spatiotemporally varying flamelets within dynamically updated zones, is adopted to decouple the interaction between the chemical reaction and turbulence locally. The transportation of conditional means of species mass fractions calculated as  $Q_a = \langle Y_a | \eta = \xi(x, t), x \in \text{zone} \rangle$  are resolved within each zone rather than the transport of  $Y_a$ , where  $\eta$  is the sampling variable in the mixture fraction space. The instantaneous mass fraction is related to  $Q_\alpha$  as,  $Y_\alpha(x, t) = Q_\alpha(\eta = \xi(x, t), x \in \text{zone}, t) +$  $Q'_{\alpha}(x \in \text{zone}, t)$ , where the conditional fluctuation  $Q'_{\alpha}$  is defined as the deviation of instantaneous value from the conditional mean. Through dynamically aggregating the CFD cells for LES flow modeling into different zones according to their similarity in terms of appropriate zone division indices, e.g., mixture fraction (*ξ*), mixture fraction variance (*ξ*˝2), reaction progress variable (*c*), streamwise coordinate (z), and Mach number (*Ma*), a homogeneous reacting state in each zone can be assumed and hence achieving a strong correlation of the fluctuation of *ξ*  and the fluctuation of  $Y_a$  in each zone. And the strong correlation would lead to  $Q^{'}_{\alpha}\approx 0$ , which avoids the approximate closure for terms related to  $\mathbf{Q}^{'}_a$  and improves the accuracy of the model consequently. It should be noted that the accuracy of DZFM relies on the choice of zone division indices, which may vary under different combustion conditions, and a general rule for zone division still needs further studies.

Substituting the  $Y_a(x,t)$  into the instantaneous species transport equation

$$
\rho \frac{\partial Y_a}{\partial t} + \rho \overrightarrow{U} \bullet \nabla Y_a = \nabla \bullet (\rho D \nabla Y_a) + \rho W_a \tag{8}
$$

it arrives,

$$
\rho \frac{\partial Q_{\alpha}}{\partial t} + \rho \overrightarrow{U} \bullet \nabla Q_{\alpha} - \rho D (\nabla \xi)^{2} \frac{\partial^{2} Q_{\alpha}}{\partial \eta^{2}} + \frac{\partial Q_{\alpha}}{\partial \eta} \left( \rho \frac{\partial \xi}{\partial t} + \rho \overrightarrow{U} \bullet \nabla \xi - \nabla
$$
  
\n•  $(\rho D \nabla \xi) \right) + \left( \rho \frac{\partial Q_{\alpha}}{\partial t} + \rho \overrightarrow{U} \bullet \nabla Q_{\alpha} - \nabla \bullet (\rho D \nabla Q_{\alpha}) \right) - \rho D \nabla \xi$   
\n•  $\nabla \left( \frac{\partial Q_{\alpha}}{\partial \eta} \right) - \rho D \nabla^{2} Q_{\alpha}$   
\n=  $\rho W_{\alpha}$  (9)

and combining with the conservation law of *ξ*,

$$
\rho \frac{\partial \xi}{\partial t} + \rho \overrightarrow{U} \bullet \nabla \xi = \nabla \bullet (\rho D \nabla \xi)
$$
\n(10)

then taking the conditional average on condition that 1)  $\xi(x, t) = \eta$  and 2) within the zone  $x \in \text{zone}$ , the transport equation of  $Q_a$  can be derived as [\[34\],](#page-12-0)

$$
\rho_{\eta} \frac{\partial Q_{a}}{\partial t} + \langle \rho u_{j} | \eta \rangle_{\text{cone}} \frac{\partial Q_{a}}{\partial x_{j}} + E_{ZFM} = \rho_{\eta} \frac{D_{a}}{D_{\xi}} \langle \chi | \eta \rangle_{\text{cone}} \frac{\partial^{2} Q_{a}}{\partial \eta^{2}} + \rho_{\eta} \left( \frac{D_{a}}{D_{\xi}} - 1 \right) M_{\eta} \frac{\partial Q_{a}}{\partial \eta} + \rho_{\eta} \langle \omega_{a} | \eta \rangle \tag{11}
$$

where  $\chi=(D_\xi+\frac{\nu_{\rm sys}}{S_{\rm c_t}}) \bullet (\nabla \xi)^2$  is the scalar dissipation,  $\langle\bullet|\eta\rangle_{zone}$  indicates a quantity conditioned on the mixture fraction within a zone,  $\rho_n = \langle \rho | \eta \rangle$  is the conditionally averaged density,  $M_{\eta} = \langle \nabla \bullet (\rho D_{\xi} \nabla \xi) | \eta \rangle_{zone}$  is the conditional diffusion. The zone conditional mean of scalar dissipation rate, 〈*χ*|*η*〉*zone* is closed using the Amplitude Mapping Closure (AMC) model [\[50\]](#page-12-0). The abbreviation  $E_{ZFM} = e_y(Q'_a) + e_q(Q_a)$  represents the terms related to the conditional fluctuation  $Q^{'}_{\alpha}$  and the macro-transport of  $Q_{\alpha}$ 

<span id="page-3-0"></span>

Fig. 1. The flowchart of the solving process of flow and combustion [\[54\]](#page-12-0).

by molecular diffusion. The first term can be neglected as  $Q^{'}_{\!a}\approx 0$  under a proper zone division scheme. And the second term,

$$
e_{Q} = \langle \rho D_{\alpha} \nabla \xi \bullet \nabla (\partial Q_{\alpha} / \partial \eta) | \eta \rangle_{zone} + \langle \nabla \bullet (\rho D_{\alpha} \nabla Q_{\alpha}) | \eta \rangle_{cone}
$$
(12)

is small for high-Re turbulent flow, where $\rho D_i \sim Re^{-1}$  following the approximate analysis in [\[51\],](#page-12-0) and is ignored in modeling supersonic combustion with DZFM [\[34,36\]](#page-12-0) and commonly neglected in the studies using CMC [\[29,32,52\].](#page-12-0) This approximation is also adopted in this paper except in [section 3.4](#page-10-0), where the DZFM model is developed to consider the molecular diffusion effect under low-Re regions.

Similar to the coarser grid used for conditional mean variables of the generic CMC model, the transport equation of *Qα* (Eq. [\(11\)\)](#page-2-0) is discretized and solved in dynamically divided zones defined by the ensemble of CFD cells and *η* space. The Operator Splitting method is applied to solve Eq. [\(11\).](#page-2-0) A finite volume method is used to solve the convective part in the divided zones considering the irregular geometric shape and the random number of CFD cells within each flamelet zones. The micro-mixing and differential diffusion of  $Q_a$  in the  $\eta$  space is solved by the finite difference method. The conditional FDF-weighted averaging method developed for high-resolution LES data [\[52,53\]](#page-12-0) is used to estimate *eQ*. And finally, the conditionally averaged chemical reaction term  $\langle \omega_{\alpha} | \eta \rangle$  is closed by the first order approximation [\[51\]](#page-12-0),

$$
\langle \omega_a | \eta \rangle = \omega_a (Q_a, Q_T) \tag{13}
$$

with the assumption of small local conditional fluctuations. The conditionally averaged temperature  $Q_T$  is estimated with a historical statistics approach [\[36,52\]](#page-12-0) rather than solving a conditional enthalpy equation with a series of unclosed conditional sub-models, therefore saving the computational cost. The flowchart of the solving process of flow and combustion is illustrated as shown in Fig. 1. At each time step, the cellbased data obtained by the flow solver are averaged over each zone and passed to the DZFM solver which solves equations of the conditional mean species and estimates conditionally mean temperature. The unconditional values of species mass fraction  $\widetilde{Y}_\alpha$ , can be obtained from the integration of conditional species mass fraction stored in the local flamelet weighted by the β-function Probability Density Function (PDF),

**Fig. 3.** Grid system of the computational domain.

 $P(η) = β(ξ̄, ξ̃<sup>2</sup>2)$  which is a function of mixture fraction  $\tilde{ξ}$  and its variance *ξ* ̃˝2.

#### *2.3. OpenFOAM-Based solver*

The governing equations are solved using an OpenFOAM [\[55\]](#page-12-0) based compressible reacting flow solver Amber, which has been validated in modeling supersonic combustion [\[34,36,56\]](#page-12-0). The convective fluxes at the surfaces are constructed by a second-order low-Mach-corrected hybrid KNP/central scheme [\[57\],](#page-12-0) which can accurately resolve turbulence away from shocks while maintaining stability near the discontinuity. Total variation diminishing (TVD) limiter vanLeer [\[58\]](#page-12-0) is used to interpolate the interface values. The temporal integration is realized by the second-order Crank-Nicholson scheme.

## *2.4. Test case and computational setups*

The numerical setup of the DLR combustor and experimental configurations are shown in Fig. 2. The air enters the combustor at  $Ma = 2$ through the entrance with a height of 50 mm and a width of 40 mm. The upper wall is divergent with a  $3^\circ$  angle after a distance of 60 mm behind the entrance. A wedge-shaped 32-mm-long and 6-mm-height strut was placed 35 mm downstream of the entrance as the flame stabilizer, where  $H_2$  is injected through a row of 15 holes on the base. The  $H_2$  orifices with the same diameter of 1.0 mm are equally distributed in the z-direction with a distance of 2.4 mm. The air is preheated with a  $H_2$ -air burner, accelerated through a Laval nozzle and then enters the combustor at the static temperature  $T = 340K$  and pressure  $p = 0.1MP$ a. The composition of the vitiated air is  $Y_{O2} = 0.232$ ,  $Y_{H2O} = 0.032$ , and  $Y_{N2} = 0.736$ . H<sub>2</sub> is injected sonically with a temperature of 250 K and a pressure of 0.1 MPa. The reader can refer to [\[37\]](#page-12-0) for more details of the experiment.

The numerical modeling is configured following the experiment. To alleviate the computational cost, one-fifth of the scramjet with only three injectors of the total fifteen in the experiment was included in the

**Fig. 2.** Numerical setup and schematic of the DLR combustor.

<span id="page-4-0"></span>

**Fig. 4.** Grid independence study based on (a) lower wall pressure under the frozen-chemistry condition and (b) centerline velocity for reacting flow.

computational domain, whose spanwise direction is treated by the periodic boundary condition. The grid system dominated by high-quality hexahedral cells is generated with the Cartesian cut-cell method [\[59\]](#page-12-0). The transition zone near the central wedge is partially filled with

tetrahedron or pyramid cells, as shown in [Fig. 3.](#page-3-0) A local refinement is used near the wedge and central zone with a minimum cell size of 0.05 mm and 0.15 mm, respectively. The boundary layer grid is filled with 15 exponential expansion layers, which grow from a 5-μm initial prism layer to satisfy the non-dimensional wall distance of  $y^+$  ~O(1). The grid convergence was verified with three meshes containing 12.6 million (M1), 27.8 million (M2), and 40.9 million (M3) cells. The lower wall pressure under the frozen-chemistry condition and the center velocity for reacting flow are shown in Fig. 4. The results show that the medium and finest mesh give similar results with the relative discrepancy of 0.95% and 6.75% for the wall pressure and center velocity, respectively. Overall, the results obtained with medium and fine mesh are closer to the experiment data [\[41\]](#page-12-0) and comparable to the numerical results from Oevermann et al. [\[3\]](#page-11-0), Cao et al. [\[60\]](#page-12-0), and Fuerby et al. [\[38\].](#page-12-0) In consideration of the computational cost, the medium-size mesh is used for the modelings if not otherwise specified. The simulation ran on Tianjin (TH-HPC4) cluster using 360 processors with a base frequency of 2.6 GHZ. The time step varied under the limitations of a maximum Courant number of 0.5 and a maximum time step of  $5 \times 10^{-8}$  s. The flow-through time (FTT) is 0.41 ms, which is estimated based on the length of the combustor (0.3 m) and the flow speed of the vitiated air (730 m/s). The modeling using the finest mesh takes about 91,000 CPU hours to ensure 5 FTTs for sampling and data statistics.

# **3. Results and discussions**

## *3.1. Model validation*

Fig. 5(a) shows the comparison between the experimental [\[37\]](#page-12-0) and numerical ( $|\nabla \rho|$ ) schlieren under the frozen-chemistry condition. The modeling results well reproduced the complex wave structure observed in the experiment, including the two oblique shock waves formed due to compression by the central wedge and the subsequent wave system due to transmission through the central jet and reflection between the upper and lower walls. The expansion and compression waves formed at the tail of the wedge were also well reproduced. In addition, shear layers are formed between the high-speed hydrogen flow ejected from the central orifice and the low-speed wake flow of the wedge and evolve into a series of vortex structures due to K-H (Kelvin-Helmholtz) instability. Furthermore, the current modeling well captured the interaction between reflected oblique shocks and the central sheer layers, which distorts the K-H vortex into larger structures, as observed in the experiment. There are another two incident shocks in the experiment,

**Fig. 5.** Comparisons of (a) schlieren and (b) velocity profiles between numerical and experimental results under frozen chemistry.

**Fig. 6.** Comparisons of (a) schlieren contoured by OH distribution and (b) profiles of velocity and temperature at various locations under combustion.

except the reflected shocks form the tip of the wedge, which leads to more complex wave structures through reflecting with walls and interaction between shock waves. The non-uniform inflow induced by the attached nozzle should be blamed for the difference in the incident shocks, as suggested by the comparative study of different boundary conditions from Potturi and Edwards [\[61\]](#page-12-0).

The distributions of average velocity at different streamwise locations are qualitatively compared in [Fig. 5](#page-4-0) (b). The modeling results reasonably agree with the experimental data, especially in the downstream region. Near the hydrogen jet and the wake interaction zone  $(x =$ 11 mm), the mean velocity drops significantly at the center as the sonic hydrogen injection is mixed with low-velocity recirculation flow formed behind the wedge. The lower-velocity region owing to the larger recirculation bubble is predicted in the current modeling and in the modeling by Oevermann et al. [\[3\]](#page-11-0) and Fureby et al. [\[38\]](#page-12-0) and some other numerical studies [\[62,63\]](#page-12-0). The discrepancy may be introduced by simplifying hydrogen injectors from 15 to 3 with periodic boundary conditions in the spanwise direction, which alters the flow in the wake of the wedge [\[64\]](#page-12-0).

Fig. 6 (a) compares the flow structure presented by the experimental and numerical schlieren for the reacting case and the flame structure contoured by the OH distribution between the OH-PLIF and numerical result. The main features of the flow structure in the experiment are well captured. The thermal expansion due to the combustion heat release affects the flow field downstream of the wedge. The recirculation flow and shear layers developed from the wedge tail are enhanced compared to the nonreacting case. With the growth of the shear layer, the expansion fan induced at the corner of the wedge weakens gradually, and consequently, the oblique shock wave formed by the convergence of shear layers disappears. In addition, the oblique shock wave reflected by walls is further reflected after contacting shear layers in the central region, while the wave is transmitted and further reflected from the up and bottom wall in the frozen-chemistry case. From the OH distribution, the lift-off phenomenon of the flame anchored by the wedge is predicted by

the current modeling based on the zone flamelet concept. Compared to the experiment, OH is distributed in a slightly narrower yet longer space. The disturbance of reflected shock waves on the flame and shear layers observed in the experimental schlieren should be the principal reason for the discrepancy. Moreover the neglect of molecular diffusion terms can also be blamed, as discussed in [section 3.4.](#page-10-0)

Comparisons between the calculated profiles of mean velocity and temperature and the measured data at three downstream locations are shown in Fig. 6 (b). It can be found that present simulations have a reasonable agreement with the experimental data and are similar to other numerical results [\[3,38,39\].](#page-11-0) Near the hydrogen jet, both modelings well predicted a wide "W" type velocity distribution due to the expansion of the recirculation zone. At the second location, the lowvelocity region in the center is narrow compared with the measured data, which was also found in the other presented simulations. At the locations far from the injection ( $x = 90$  mm), the flat velocity distribution due to turbulent mixing is well captured by all the modelings. For the mean temperature, the predictions near the tail of the wedge  $(x = 11$ mm) of the current and other studies match well with the measurement, except the result given by [\[38\]](#page-12-0) slightly overpredicted the lift-off distance of the flame. In the middle of the combustion chamber  $(x = 58 \text{ mm})$ , the predicted mean temperature profile shows a double-peak structure consistent with the thin split flame sheets in [Fig. 5](#page-4-0) (a). The flame sheets have been merged near the combustor exit ( $x = 166$  mm), resulting in a single peak temperature profile as observed experimentally. The comparison shows that the modeling by Oevermann [\[3\]](#page-11-0) with the RANS method predicted a much more distributed flame structure than other LES simulations by Zhang et al. [\[39\]](#page-12-0) and Fureby. Moreover, the agreements of all the presented LES results are overall good. Considering the difference in sub-grid model, turbulent combustion models, and combustion chemistry adopted in these LES studies, such a variety of predictions can be expected.

#### *3.2. Flow and mixing analysis*

Fig. 7 shows the vortex structure and mixture fraction (ξ) distribution in the wake region of the wedge under frozen chemistry. From Fig. 7 (a), the two shear layers developed from the base of the wedge are rolled up due to K-H instability and interact with the asymmetric oblique shock train to form large-scale vortexes, which then shred in the form of smallscale disordered vortexes under the second instability. The above flow instability process controls the mixing between the hydrogen-enriched wake flow and the ambient air. As shown in Fig.  $7$  (b), the mixing of hydrogen and air is mainly controlled by the entrainment of large-scale spanwise vortices near the wedge ( $x = 20 \sim 40$  mm), where the mixture

fraction decreases rapidly, but most of the region is still under a fuel-rich condition. The shedding from downstream (x *>* 60 mm) strengthens the streamwise vortexes and enhances the small-scale mixing, as indicated by the much more homogeneous spatial distribution of mixture fraction.

Fig. 8 shows the evolution of vortex structure and mixture fraction in the wake region for the combustion case. For the combustion case, the mixing is affected by not only the shear instability but also the heat imposition. The volumetric expansion due to heat release causes wider shear layers and a larger wake region but also constrains the development of quasi-two-dimensional large-scale spanwise vortices. The baroclinic effect between the reacting shear layer induces randomly oriented small vortexes in the jet wake region behind the wedge.

<span id="page-7-0"></span>![](_page_7_Figure_2.jpeg)

**Fig. 9.** Contours of transport index (vs, baro, dila, diff) of vorticity for combustion and frozen-chemistry cases.

Two small-scale vortex streets adjacent to the central vortexes are formed along the shear layers from the boundary layer separation point on the inclined surface of the wedge. The vorticity magnitude of two vortex streets increases as transferred downstream, leading to a more intense interaction with the flame. Such interaction rolls up and merges the flame sheet, which finally transforms into a pulsating and intermittent pattern. From [Fig. 8](#page-6-0) (b), the mixture fraction at the corresponding location is higher than that in the frozen-chemistry case. The hydrogen-rich wake flow is stirred by relatively small vortexes inside the flame sheets denoted by  $Y_{OH} = 0.05$ , leading to a more homogeneous mixture downstream.

A further analysis to identify the mechanisms of mixing can be conducted by looking at the compressible vorticity transport equation:

$$
\frac{D\omega}{Dt} = \underbrace{(\omega \cdot \nabla) - \omega(\nabla \cdot u) + (\nabla \rho \times \nabla \rho)/\rho^2}_{\text{vs}} + \underbrace{\nu \nabla^2 \omega}_{\text{Baro}} \tag{14}
$$

The terms on the right-hand side represent the four main physical mechanisms that contributed to the vorticity evolution through vortex stretch **VS**, dilatation **Dila**, baroclinic torque **Baro**, and diffusion **Diff**, respectively. To have an insight on the effects of different terms on vorticity evolution, the transport index obtained through the inner product between the original transport term and the unit vector along vorticity (eg. dila =  $(\omega/||\omega||) \cdot Dila$ ) are shown in Fig. 9. In both the reacting and chemistry-frozen cases, the vortex stretch and dilatation play an important role of vorticity transport and evolution of vortices. In the reacting case, the heat release leads to volume expansion of the upstream region near the strut, which weakens the positive effect of vortex stretch and strengthens the negative effect of dilatation on

![](_page_7_Figure_8.jpeg)

**Fig. 10.** Streamwise variation of mixing efficiency and contours of  $\xi_{st} = 0.028$ (inset) for the frozen-chemistry and combustion cases.

vorticity and depresses the large-scale spanwise vortex behind the strut as that in the non-reacting case. Meanwhile, the vorticity magnitude of two vortex streets along the flame surface increases because of the amplification of baroclinic torque due to misalignment between the density gradient and the pressure gradient across the flame, as shown in

![](_page_8_Figure_1.jpeg)

**Fig. 11.** Contours of instantaneous flame temperature and species on the central z-slice overlaid with the TFI contour line of  $\pm$  0.5.

[Fig. 8.](#page-6-0) The diffusion term diff represents the effect of viscosity is much lower than others, which reduces vorticity through diffusion and dissipation, especially in the reacting case.

To quantitatively analyze the effect of heat release on the mixing, the streamwise variation of mixing efficiency (*ηmix*) in the frozen-chemistry and combustion cases are compared in [Fig. 10.](#page-7-0) The mixing efficiency averaged over n sampling time steps is calculated as [\[65\],](#page-12-0)

$$
\eta_{mix} = \frac{1}{n} \sum_{n} \frac{\dot{m}_{\text{fuel,mixed}}}{\dot{m}_{\text{fuel, total}}} = \frac{1}{n} \sum_{n} \frac{\int (\rho u \xi_{\text{react}}) \bullet dA}{\int (\rho u \xi) \bullet dA}
$$
(15)

where *Y<sub>H2</sub>* is the hydrogen mass fraction, and *ξ*<sub>react</sub> is defined as the mass fraction of the least available reactant (fuel or oxygen depending on the global equivalence ratio) that would react if a complete reaction took place without further mixing.. When the local mixture fraction is lower than the stoichiometric mixture fraction  $\xi_{st}$ , it is considered that  $\xi_{react}$  = *ξ*, otherwise  $\xi_{\text{react}} = \xi_{\text{st}}(1 - \xi)/(1 - \xi_{\text{st}})$ . From [Fig. 10,](#page-7-0)  $η_{\text{mix}}$  increases rapidly near the end of the wedge, where hydrogen is quickly mixed with the surrounding air with the aid of the strong shear flow and the recirculation zone. The larger recirculation zone in the combustion case causes better near-field mixing, where the mixing efficiency increases faster than that in the frozen-chemistry case. After the recirculation zone, the entrainment of air by the large-scale spanwise vortexes makes the mixing efficiency in the frozen-chemistry case supersede that in the combustion case, while the underdevelopment of large-scale vortexes inhibits the rise of mixing efficiency in the combustion case. It can be considered that the convective transport of the large-scale spanwise vortexes disperses the fuel rapidly and therefore dominates the mixing efficiency, while the turbulent diffusion enhanced by the small-scale vortexes is vital for homogenous mixing between fuel and oxygen indicated by a homogeneous and low distribution of mixture fraction in the downstream region as shown in Fig.  $7$  and [Fig. 8.](#page-6-0) The baroclinic

![](_page_8_Figure_7.jpeg)

**Fig. 12.** Reaction path diagram of hydrogen-air premixed flame (a) at low temperature and (b) at high temperature.

torque and thermal expansion due to heat release in reacting flow induce more diffusive small vortexes but suppress the formation of large-scale vortexes in the plume [\[66\],](#page-12-0) resulting in a longer mixing distance for the combustion case. The inset in [Fig. 10](#page-7-0) illustrates the tortuous and broken contours of  $\xi_{st} = 0.028$  due to large-scale vortex which enhancing the mixing process, especially for the frozen flow.

# *3.3. Premixed flame mode and TCI mode*

Fig. 11 shows the contours of flame temperature and species on the central z-slice and the distribution of flame mode based on improved TFI (Takeno flame index) [\[67\].](#page-12-0) In addition to distinguishing the premixing and diffusion modes by the diffusion direction (concentration gradient) between oxygen and fuel, the improved TFI also defines the rich and lean region according to the stoichiometric mixture fraction as,

$$
\text{TFI} = \begin{cases} \left(\frac{\xi - \xi_{st}}{|\xi - \xi_{st}|}\right) \bullet \frac{1}{2} \left(1 + \frac{\nabla Y_{H2} \bullet \nabla Y_{O2}}{|\nabla Y_{H2} \bullet \nabla Y_{O2}|}\right) (\xi \neq \xi_{st}) \\ \frac{1}{2} \left(1 + \frac{\nabla Y_{H2} \bullet \nabla Y_{O2}}{|\nabla Y_{H2} \bullet \nabla Y_{O2}|}\right) (\xi = \xi_{st}) \end{cases}
$$
(16)

According to Eq. (16), the flame with TFI*>*0.5 is in a rich premixed mode, and the one with TFI lower than − 0.5 is in a lean premixed mode, otherwise in a diffusion mode. From Fig. 11, the central hydrogen jet and the shear layer have a relatively low temperature and are in the rich and lean premixed modes, respectively. The rich premixed flame is formed by intensive near-field mixing by the recirculation zone, as illustrated in [Fig. 10](#page-7-0). The small-scale vortex street produces the lean premixed flame along the shear layers. The reaction paths sampled at several representative points are shown in Fig. 12. The heat release in the low-temperature premixed flame region is mainly contributed by low-activation-energy reactions  $H_2 + O_2$  =>  $HO_2 + H$  and  $H + O_2 + M$ =>HO<sub>2</sub> + M. With the massive generation of HO<sub>2</sub>, H<sub>2</sub>O<sub>2</sub> is generated via  $2HO_2$  = >  $H_2O_2 + O_2 \cdot H_2O_2$  and  $HO_2$  further generate OH and H through chain branch reactions. The radicals OH and H generated in the lowtemperature premixed flame region were transported into the hightemperature diffusion flame region to induce a thermal explosion of self-accelerating reactions. In the high-temperature reaction region between the low-temperature premixed regions, the reaction is dominated by chain branching reactions H2 + OH=*>*H2O + H and O + H2=*>*H + OH, which consumes hydrogen and generates rich active radicals and H2O in the central diffusion flame region. Near the domain exit, local flame quenching due to weak reactions renders an intermittent flame pattern, as shown in Fig. 11.

[Fig. 13](#page-9-0) (a) shows the distribution of the active intermediate OH

<span id="page-9-0"></span>![](_page_9_Figure_2.jpeg)

Fig. 13. (a)Y<sub>OH</sub> distributed in the mixture fraction space colored by x-coordinates and Mach number and (b) profiles of the conditional means of reactive scalars in different zones.

radical in the mixture fraction space. The significant difference in the YOH-ξ probed at different locations suggests that applying a single flamelet for the whole physical space may introduce remarkable errors in describing the reacting states in a supersonic flame. After grouping the sampling states in terms of the streamwise coordinate and Mach number, the scattering of  $Y_{OH}$  distribution within each group was significantly reduced. The strong correlations between the local reacting states denoted by  $Y_{OH}$  and mixture fraction within each subgroup

<span id="page-10-0"></span>![](_page_10_Figure_1.jpeg)

**Fig. 15.** Results of (a) instantaneous flame structure and (b) mean flame temperature with..*e*<sub>Q</sub>

validate the physical correctness of zone-based flamelet. [Fig. 13](#page-9-0) (b) shows the evolution of the conditional profiles of reactive scalars in different zones divided by x-coordinates, which indicates the variation of flame and TCI models in the physical space, as discussed above. Therefore, dynamically partitioning the flow field based on multiple zone division indices can capture the distribution of different reaction states of the flame, effectively reduce conditional fluctuations, and make the first-order closure assumption more valid.

[Fig. 14](#page-9-0) quantitatively measures the turbulence-chemistry interaction modes by the Borghi diagram  $[68]$ . Damköhler number defined as Da = *τ*<sub>*t*</sub>/*τ*<sub>*c*</sub> represents the ratio of the turbulent time scale  $\tau$ <sub>*t*</sub> =  $k/\varepsilon$  to the chemical time scale *τc*, which is determined as the reciprocal of CEMA (Chemical explosive mode analysis) index [\[69,70\].](#page-12-0) Karlovitz number is defined as  $\tau_c/\tau_\eta = \delta_L^2/l_\eta^2$  to weigh the chemical time scale to the Kolmogorov time scale  $\tau_{\eta} = (\nu/\epsilon)^{1/2}$ , and scale the laminar flame thickness *δL* to the Kolmogorov space scale *lη*. The Reynolds number *Re* are related to Da and Ka by  $Re (\tau_t/\tau_\eta)^2 = Da^2 \bullet Ka^2$ . The above dimensionless

![](_page_10_Figure_6.jpeg)

**Fig. 16.** Comparisons of (a) time averaged mass-flux-weighted spatial-averaged dila and vortex structure colored by mixture fraction (inset) and (b) mixing efficiency with and without the *eQ* correction.

parameters divide the flame into three TCI modes: flamelet mode (Ka *<* 1 and Da *>* 10), thin reaction mode (Ka *<* 100 and Da *>* 10), and slow chemistry mode (Da *<* 10). The statistical results show that the flamelet mode accounts for 56.4%, the thin reaction mode accounts for 28.9%, and the slow chemistry mode accounts for 14.7%. The flamelet mode is mainly in the reacting shear/mixing layer, where the temperature is high and reactions are active under near unity equivalence ratios. The thin reaction mode mainly exists in the downstream flame region, where the eddy scale is reduced to be comparable to the thickness of laminar flame, allowing them to penetrate into the reaction zone to thicken the flame front. The slow chemistry mode mainly locates in the lowtemperature zone behind the wedge and near the exit, where the flame speed is lower than the turbulent pulsation velocity.

## *3.4. Low-Re development of DZFM*

As shown in [Fig. 14,](#page-9-0) there are considerable amounts of flame zones under relatively low Reynolds numbers, such as the flame immediately behind the wedge, where the assumption of small viscosity and diffusion coefficients for closure of Eq. [\(11\)](#page-2-0) is invalid. Therefore, it is necessary to include the molecular diffusion terms  $(e_0)$  in the transport of  $Q_\alpha$ , i.e., the evolution of zone flamelets. The terms of  $e_Q$  (Eq.  $(12)$ ) have the effect of smoothing the flamelets in neighboring zones by molecular diffusion. Fig. 15 shows the instantaneous flame structures and time-averaged temperature with and without the model correction. After including *eQ*, the lift-off distance increases, and the split flame sheets in the two shear layers merge earlier. Meanwhile, the flame temperature increases in the center of the jet wake, albeit with a lower temperature in the shear <span id="page-11-0"></span>layer near the wedge. Overall, the inclusion of  $e_0$  better reproduces the experiment.

[Fig. 16](#page-10-0) compares the vortex structure and mixing efficiency with and without the  $e_0$  correction. The large-scale spanwise vortexes are observably enhanced near the base of the wedge with  $e_0$ . The mixture efficiency increases faster under the strengthened entrainment of the large-scale vortexes, which dominate the mixing, as pointed out before. To quantify the thermal expansion effect on vorticity, the time-averaged integration on the cross-section is calculated for the transport index  $dila = (\omega / ||\omega||) \cdot Dila$  with the equation

$$
\overline{dila}_x = \frac{1}{n} \sum_n \frac{\int (\rho \mathbf{u} \times dila) \bullet dA}{\int (\rho \mathbf{u}) \bullet dA}
$$
(17)

As shown in [Fig. 16](#page-10-0) (a), for the DZFM with  $e_0$  correction the  $\overline{dila}$ <sub>x</sub> are larger near the root of the flame, which indicts the weakening of the dilatation effect. The strengthened vortexes can be attributed to the downstream movement of the flame anchoring position when the suppression of vorticity by thermal expansion weakens in the flame lift-off stage. The inclusion of  $e_0$  considers the inter-zone diffusion effect, which smoothes the local peak in flame temperature and forms a more distributed flame front in the low-Re flame base region. The subsequent mixing enhancement promotes the combustion consumption of the fuel and consequently increases the temperature in the center and downstream region, as shown in [Fig. 15.](#page-10-0) The above improvement in capturing the flame structure makes it agree better with the experimental observation.

#### **4. Conclusions**

Based on the dynamic zone flamelet model (DZFM), the turbulent combustion in the DLR combustor is simulated with three-dimensional IDDES adopting a detailed hydrogen/air combustion mechanism. For the current examined supersonic jet flame, the convective transport of the large-scale spanwise vortexes dominates the mixing efficiency, while the turbulent diffusion enhanced by the small-scale vortices is vital for homogenous mixing between fuel and oxygen. The larger recirculation zone in the combustion case causes better near-field mixing, but the developed large-scale spanwise vortexes make the mixing efficiency in the frozen-chemistry case supersede that in the combustion case after the recirculation zone. Analysis based on improved TFI shows that the central hydrogen jet and the shear layer are in the rich and lean premixed modes, respectively. The intensive near-field mixing by the recirculation zone produces a rich premixed flame mode, and the smallscale vortex street produces the lean premixed flame along the shear layers. Reaction path analysis shows that the radicals OH and H generated from the low-activation-energy reactions in the low-temperature premixed flame region were transported into the high-temperature diffusion flame region to induce a thermal explosion of selfaccelerating reactions. The significant difference in the  $Y_{OH}$ - $\xi$  probed at different locations suggests that applying a single flamelet for the whole physical space may introduce remarkable errors in describing the reacting states in a supersonic flame. Dynamically partitioning the flow field based on multiple zone division indices can effectively reduce conditional fluctuations and make the first-order closure assumption more valid. The Borghi diagram shows that the flame zone consists of 56.4% flamelet mode, 28.9% thin reaction zone mode, and 14.7% slow chemistry zone mode. The flamelet mode is mainly in the reacting shear/mixing layer, the thin reaction mode mainly exists in the downstream flame region, and the slow chemistry mode mainly locates in the low-temperature zone behind the wedge and near the exit.

Considering the vast existence of low-Re regions even in a supersonic combustor, DZFM is modified to include the molecular diffusion effect. The inclusion of  $e_0$  considers the inter-zone diffusion effect, which smoothes the local peak in flame temperature and forms a more distributed flame front in the low-Re flame base region. The subsequent

mixing enhancement promotes the combustion consumption of the fuel and a shorter flame length. The better agreement with the experimental observation suggests that the molecular diffusion may have a nonnegligible effect even for supersonic flame anchored by a low Re number zone.
